Multifunctional Gadolinium-Doped Mesoporous TiO$_2$ Nanobeads: Photoluminescence, Enhanced Spin Relaxation, and Reactive Oxygen Species Photogeneration, Beneficial for Cancer Diagnosis and Treatment

Roghayeh Imani, Ralf Dillert, Detlef W. Bahnemann, Meysam Pazoki, Tomaž Apih, Veno Kononenko, Neža Repar, Veronika Kralj-Iglič, Gerrit Boschloo, Damjana Drobne, Tomas Edvinsson,* and Aleš Iglič*

Material with controllable multifunctional abilities for optical imaging (OI) and magnetic resonant imaging (MRI) that also can be used in photodynamic therapy are very interesting for future applications. Mesoporous TiO$_2$ sub-micrometer particles are doped with gadolinium to improve photoluminescence functionality and spin relaxation for MRI, with the added benefit of enhanced generation of reactive oxygen species (ROS). The Gd-doped TiO$_2$ exhibits red emission at 637 nm that is beneficial for OI and significantly improves MRI relaxation times, with a beneficial decrease in spin–lattice and spin–spin relaxation times. Density functional theory calculations show that Gd$^{3+}$ ions introduce impurity energy levels inside the bandgap of anatase TiO$_2$, and also create dipoles that are beneficial for charge separation and decreased electron–hole recombination in the doped lattice. The Gd-doped TiO$_2$ nanobeads (NBs) show enhanced ability for ROS monitored via $\bullet$OH radical photogeneration, in comparison with undoped TiO$_2$ nanobeads and TiO$_2$ P25, for Gd-doping up to 10%. Cellular internalization and biocompatibility of TiO$_2$@xGd NBs are tested in vitro on MG-63 human osteosarcoma cells, showing full biocompatibility. After photoactivation of the particles, anticancer trace by means of ROS photogeneration is observed just after 3 min irradiation.
1. Introduction

In recent years, TiO$_2$ was regarded as a potential photosensitizer in the field of photodynamic therapy (PDT) due to its high chemical stability, excellent biocompatibility when not irradiated, and photoreactivity.$^{[1-3]}$ The photocytotoxicity of TiO$_2$ to malignant cells, based on its reactive oxygen species (ROS) photogeneration ability under UV-A irradiation, was reported by different groups.$^{[4-9]}$ It has been reported that various ROS, such as superoxide (O$_2^{-}$*), singlet oxygen (O$_2$), hydroxyl radical (OH$^•$), hydroperoxyl radical (HO$_2$*), and hydrogen peroxide (H$_2$O$_2$), are generated on the TiO$_2$ surface upon UV-A irradiation in aqueous solutions.$^{[10]}$ ROS are capable of destroying bacteria, viruses, and cancer cells, where manipulation of ROS levels with exogenous agents has been reported to be an efficient way to destroy cancer cells.$^{[11]}$ where the low-lying energy of the photogenerated hole in TiO$_2$ makes the generation of *OH specifically effective. Cancerous cells normally contain an elevated level of ROS and are therefore more sensitive to any further ROS increase.$^{[11]}$ In the tumor region, externally applied radiation stimulates increased production of ROS by the photosensitizer, which is beneficially used in PDT.$^{[12]}$ TiO$_2$ is one of the most efficient of all nanoparticulate systems in performing ROS photogeneration, which is the most important prerequisite for practical application in photodynamic therapy.$^{[13]}$ TiO$_2$, however, is not intrinsically suited for imaging purposes, as it has very faint fluorescence for optical imaging (OI), and it has dominant Raman bands in a very low energy region ($\approx$100–300 cm$^{-1}$); it is not magnetic and it does not have a substantially large atomic number to have a significant contrast in magnetic resonance imaging (MRI) and X-ray measurements.$^{[2,3,14]}$ Therefore, a current challenge to the use of TiO$_2$ nanostructures as a photosensitizer is the addition of imaging agents (e.g., contrast), which have to be incorporated into TiO$_2$ to ensure reliable tracking of TiO$_2$ delivery. To avoid damage to normal cells, monitoring and tracking of the TiO$_2$ localization and concentration in the cell tissues around the cancerous cell before irradiation, as well as during irradiation are vital.$^{[15-17]}$ The powerful future implementation of TiO$_2$ in photodynamic therapies is conditional on modification of TiO$_2$ nanostructures to gain maximum imaging and therapeutic efficacy of TiO$_2$ nanostructures, a compromise among ROS generation, endocytosis, and low toxicity to nontarget cells and cell imaging properties.$^{[16]}$

Among different imaging methods, OI has by far the greatest resolution that can visualize structures on the subcellular scale.$^{[18-20]}$ MRI has the advantage of being widely used as diagnostic, noninvasive, or minimally invasive tools for imaging.$^{[21]}$ The combination of MRI and OI in one MRI–OI probe is particularly useful. Combined MRI–OI agents have great application potential in selective tumor labeling for oncological diagnosis and surgery.$^{[22,23]}$

Recently, surface labeled TiO$_2$ nanoparticles, nanotubes, or nanoprobes with fluorescent dye or magnetic resonance contrast agents have been successfully prepared and utilized for cell imaging through OI or MRI.$^{[23,14]}$ but surface modifications of TiO$_2$ with organic capping ligands significantly lower the ROS photogeneration activity of TiO$_2$.$^{[24]}$ To address this issue, TiO$_2$ photocatalysts are often produced in the form of a framework that can be calcined at high temperatures, to ensure a clean surface and well developed crystallinity$^{[25]}$ therefore, for effective use of TiO$_2$ in targeted cancer therapy, surface coverage with an imaging agent is not a good solution. For solving this problem, incorporation of imaging elements inside the crystalline structure of TiO$_2$ could be a better solution. Different elements such as Fe, Co, Ni, etc., could be incorporated into crystalline structure of TiO$_2$ as a medical imaging agent. In the last few years, lanthanide (which are often collectively known as the rare earth (RE) elements) nanocomounds have attracted considerable attention as optical imaging probes.$^{[25]}$ Currently, gadolinium (Gd) compounds are used as a commercial MRI contrast agent in hospitals.$^{[21]}$ as well as luminescent nanomaterials that incorporate RE ions within their structures, and have also gained considerable attention as optical imaging probes in medicine.$^{[19]}$ Many efforts have been devoted to exploring TiO$_2$-based phosphors with various morphologies and dopants.$^{[26-30]}$

One of the drawbacks of nanomaterials is general nanotoxicity. The optimal “safe” size is based on numerous examples in literature, which show clearly that 100 nm is the distinct cut-off size below which atypical surface reactivity arises and causes normal nanoscale toxicity.$^{[5,31]}$ Based on this critical feature, recently we have engineered mesoporous TiO$_2$ nanobeads (TiO$_2$ NBs) having a size greater than 100 nm, to avoid normal nanotoxicity, and on the other hand keeps the high surface area comparable to nanometer-size particles by utilizing mesoporosity. TiO$_2$ NBs totally were biocompatible in the absence of irradiation that also
possesses a high ability for ROS photogeneration and cancer cell destruction under UV-A irradiation.[5,32] Here we report doping of TiO\textsubscript{2} NBs with the rare earth element Gd to add multifunctional OI–MRI properties, as well enhanced ROS photogeneration capacity to the TiO\textsubscript{2} NBs.

The photocatalytic activities of the TiO\textsubscript{2}@xGd NBs in terms of ROS photogeneration were quantified via \textsuperscript{1}OH radical measurement with fluorescence probe and compared with a standard TiO\textsubscript{2} powder (P25). The details of the bandgap states introduced by the Gd-doping, and the consequences for the photoluminescence (PL) and photocatalytic enhancement are investigated and supported by density functional theory (DFT) calculations. Finally, the MG-63 in vitro cell culture was used to study the internalization potential and cytotoxicity of TiO\textsubscript{2}@xGd NBs. We discuss the advantage of TiO\textsubscript{2}@xGd NBs for simultaneous imaging and PDT of cancer cells. Data presented here, proving a notable biocompatibility and multifunctionality of TiO\textsubscript{2}@xGd NBs for cancer diagnosis and treatment, are very interesting for future applications.

2. Results and Discussion

2.1. Morphological and Structural Description of TiO\textsubscript{2}@xGd NBs

The morphological characteristics analyzed by scanning electron microscopy (SEM), transmission electron microscopy (TEM), and elemental composition/distribution by energy-dispersive X-ray spectroscopy (EDS) of TiO\textsubscript{2} NBs, TiO\textsubscript{2}@5\%Gd NBs, and TiO\textsubscript{2}@10\%Gd NBs are shown in Figure 1, where all three structures consist of submicrometer nanospheres with a rough surface, while a few distinct differences between the Gd-doped TiO\textsubscript{2} NBs and the pure TiO\textsubscript{2} NBs can be observed: i) the average diameter of Gd-doped TiO\textsubscript{2} NBs (∼800 nm) is higher than that of the undoped TiO\textsubscript{2} NBs (∼500 nm), ii) Gd-doped TiO\textsubscript{2} NBs have a smoother surface compared to pure TiO\textsubscript{2} NBs, and iii) nanostar clusters appeared on top of Gd-doped TiO\textsubscript{2} NBs (marked with a red circle in Figure 1g). A number of nanostar clusters on TiO\textsubscript{2}@10\%Gd NBs increased significantly compared to TiO\textsubscript{2}@5\%Gd NBs, and no trace of nanostar clusters can be seen on TiO\textsubscript{2} NBs surfaces (Figure 1a,d,g).[33] High magnification TEM measurements were conducted to obtain more information about the structural properties of nanostar clusters (Figure 1j,k). TEM images indicated the nanostar clusters are composed of two kinds of structures: i) nanocrystals with different shapes and an average size of ∼5 nm) and ii) very small, packed semi-crystalline nanoparticles of ∼5 nm in dimension (Figure S1, Supporting Information).

A structural transformation was observed in the case of TiO\textsubscript{2} NBs having a high Gd content (exceeding 10\%, TiO\textsubscript{2}@15\%Gd and TiO\textsubscript{2}@20\%Gd). As is apparent in the SEM images (Figure S2a,d, Supporting Information) no spheres were formed in these structures, where TEM analysis showed that TiO\textsubscript{2}@15\%Gd NBs are composed of very small (∼5 nm) semicrystalline nanoparticles (Figure S2b, Supporting Information), while TiO\textsubscript{2}@20\%Gd NBs are composed of densely packed crystalline nanoparticles with a visible crystalline plane (Figure S2e, Supporting Information). The Gd-doping concentration in the synthesized structures was found by an energy-dispersive X-ray analysis during SEM imaging to be very close to that in the precursor solution (Figures S3–S7, Supporting Information).

The X-ray diffraction (XRD) results (Figure 2a) confirmed that anatase is the predominant phase for TiO\textsubscript{2} NBs, TiO\textsubscript{2}@5\%Gd NBs, and TiO\textsubscript{2}@10\%Gd NBs and all (101), (004), (200), (105), (211), (213), (204) peaks observed in the XRD patterns are related to the anatase phase of TiO\textsubscript{2} (JCPDS number: 21-1272).[34,35] However, the crystallinity was reduced by increasing the Gd amount, in agreement with previous observations.[35] The relative crystallite sizes of the structures were calculated with the Debye–Scherrer formula,[34] showing that the size of the nanocrystals that build the NBs increase with increasing Gd amount, amounted to 21 nm for TiO\textsubscript{2} NBs, 30 nm for TiO\textsubscript{2}@5\%Gd NBs, and 42 nm for TiO\textsubscript{2}@10\%Gd NBs. A small amount of Gd doping (5 and 10 mol\%) resulted in an increased crystalline size for anatase titania, while crystallinity decreased with high doping concentration (15 mol\%). This variation in the anatase crystal size with respect to Gd-doping can be rationalized regarding the ionic radii of the dopant and matrix. There are strong differences in the chemical properties of Gd\textsuperscript{3+} and Ti\textsuperscript{4+}, and the mismatch in the ionic radii (180 ± 6 and 68 pm, respectively) makes it increasingly difficult to substitute Ti\textsuperscript{4+} by Gd\textsuperscript{3+} within the anatase lattice without perturbing the structure. Depending on the concentration, Gd\textsuperscript{3+} ions can then adopt different environments when incorporated within titania, where Gd is in low concentration will likely enter the titania lattice, which is the reason for the increased crystal size.[30] It has also been reported that when the lanthanide content increases, most dopant cations will be incorporated close to the semiconductor crystallite surface in a glass-like environment, inhibiting the host material crystallization process.[37]

For higher concentrations, sufficient Gd and oxygen content can then result in a beneficial environment for the creation of new crystalline phases with RE participation. In the highest concentrations adopted here, TiO\textsubscript{2}@20\%Gd, an outer crystalline structure is also formed (Figure 3c) that likely can be attributed to the new crystalline phase apparent in the XRD pattern for this sample (Figure 2b). In the XRD pattern of TiO\textsubscript{2}@20\%Gd NBs, the (105) and (213) peaks can be assigned to reflections from the anatase phase of TiO\textsubscript{2}, while the predominant phase for this structure is the pyrochlores phase, with (004) and (102) peaks that can be assigned to Gd\textsubscript{4}Ti\textsubscript{5}O\textsubscript{12} and peak (551) assigned to Gd\textsubscript{2}Ti\textsubscript{2}O\textsubscript{7} (JCPDS number: 21-1272).[38,39] In both figures, peaks named FTO (fluorine-doped tin oxide conducting glass) are attributed to the sample substrate.

The Raman spectra of the TiO\textsubscript{2} NBs, TiO\textsubscript{2}@5\%Gd NBs, TiO\textsubscript{2}@10\%Gd NBs, and TiO\textsubscript{2}@15\%Gd NBs match with the anatase phase (Figure 2c).[40] The anatase has six Raman active modes (A\textsubscript{1g} + 2B\textsubscript{1g} + 3E\textsubscript{g}), which all appear in the Raman spectra of TiO\textsubscript{2} NBs and TiO\textsubscript{2}@5\%Gd NBs (Figure 2c). Among them, three E\textsubscript{g} modes are centered around 144, 197, and 640 cm\textsuperscript{-1} (designated E\textsubscript{g1}, E\textsubscript{g2}, and E\textsubscript{g3}), and two B\textsubscript{1g} modes located at 399 and 515 cm\textsuperscript{-1} (designated...
Because the peak positions of $A_{1g}$ and $B_{1g(2)}$ are almost the same, we do not differentiate them here. The $E_{g1}$ mode that corresponds to the symmetric lattice angular vibration is the strongest characteristic peak of anatase, as seen in Figure 2c. By increasing the Gd amount, the intensity of this mode decreased monotonically, in good agreement with decreased anatase crystallinity upon Gd doping.\cite{35} In the Raman spectrum of TiO$_2$@20\%Gd NBs (Figure 2d), the Raman modes assigned to the anatase phase were not observed but instead showed Raman active modes at 264 and 450 cm$^{-1}$ characteristics of Gd$_2$Ti$_2$O$_7$.\cite{38,41} in very good agreement with XRD results.

2.2. Optical and Magnetic Resonance Imaging of TiO$_2$@xGd NBs

PL spectra show that the emission of Gd-doped TiO$_2$ spheres was dominated by a red emission peak at 636 nm upon UV excitation (Figure 3a), which previously has been assigned to

Figure 1. a,d,g) SEM, b,e,h) TEM, and c,f,i) EDS images of obtained structure: a–c) TiO$_2$ NBs, d–f) TiO$_2$@5\%Gd NBs, and g–i) TiO$_2$@10\%Gd NBs; red circle indicating the nanostar clusters in TiO$_2$@10\%Gd NBs. j) TEM and k) HRTEM images of nanostar clusters, the crystalline plane of the nanoparticle is shown in (k).
Figure 2. XRD spectra of synthesized structures: a) TiO$_2$ NBs, TiO$_2$@5%Gd NBs, TiO$_2$@10%Gd NBs, TiO$_2$@15%Gd NBs, and b) TiO$_2$@20%Gd NBs; Raman shift spectra of synthesized structures: c) TiO$_2$ NBs, TiO$_2$@5% Gd NBs, TiO$_2$@10% Gd NBs, and TiO$_2$@15% Gd NBs, and d) TiO$_2$@20% Gd NBs. Corresponding Raman-active modes are labeled in the figure.

Figure 3. a) Room temperature photoluminescence spectra of Gd$^{3+}$-doped TiO$_2$ spheres upon UV (320 nm) excitation. b) $^1$H NMRD profile for TiO$_2$@15%Gd NBs at 298 K. c,d) Dependence of resulting 7-hydroxycoumarin concentration to the irradiation time; c) in the absence of H$_2$O$_2$, d) in the presence of H$_2$O$_2$. Concentration was calculated from the fluorescence measurement of $0.1 \times 10^{-3}$ m coumarin.
an atomic-like f-f transition. In line with this, we observe an increasing emission intensity with increasing Gd amount, and the strongest emission was observed in the case of TiO$_2$@15%Gd NBs, which is attributed to the structure of the NBs. According to XRD, TEM, and the Raman results, we can conclude that the TiO$_2$@15%Gd NBs are primarily a mixture of anatase and amorphous phases. It has been suggested that the semi-crystalline TiO$_2$ structure is an excellent host for RE$^{3+}$ ions and here seen to show highest PL intensity for 15% Gd, while higher Gd content instead shows a Gd$_3$Ti$_2$O$_7$ structure from Raman and XRD. The rich spectral properties of certain RE ions, when incorporated in host materials, are highly attractive in many ways. However, RE ions alone are weakly fluorescent due to the parity forbidden f-f transitions. Lanthanides possess a unique orbital arrangement resulting in a large Stoke’s shift and a narrow emission and have therefore been a natural choice for imparting photoluminescence. TiO$_2$ lattices have proved to be an excellent host material for RE ions due to their good thermal, chemical, and mechanical stabilities. Titania nanocrystals surrounded by regions of amorphous titania have previously been proposed to act as effective light-harvesting antennae to absorb light and transfer energy to RE ions, which emit intense sharp luminescence, and also that a half-filled electronic configuration of RE dopant is beneficial for improving the photocatalytic activity of TiO$_2$.

Paramagnetic gadolinium(III) ions (Gd$^{3+}$) possess seven unpaired electrons, which can efficiently alter the relaxation time of surrounding water protons, and have been widely used in routine clinical imaging as MRI contrast agents. To investigate how Gd$^{3+}$ doped TiO$_2$ NBs would function as contrast agent in MRI, the relaxation times ($T_1$, $T_2$) of TiO$_2$@Gd NBs were measured in a static magnetic field at 400 MHz (Table S1, Supporting Information). Both the spin–lattice relaxation time ($T_1$) and the spin–spin relaxation time ($T_2$) were shortened for Gd$^{3+}$ doped TiO$_2$ NBs in comparison with pure TiO$_2$ NBs. However, relaxation rates $R_1 = 1/T_1$ and $R_2 = 1/T_2$ enhancements expressed as millimolar relaxivities $r_1$ and $r_2$ were significantly different for various samples where shape, size, crystallinity, and surface arrangement of the MRI contrast agent have a strong effect on longitudinal and transverse relaxation times. Based on the data presented in Table S1 (Supporting Information), there was no high $T_1$ shortening effect in the cases of TiO$_2$@5%Gd NBs, TiO$_2$@10%Gd NBs, and TiO$_2$@20%Gd NBs, while TiO$_2$@15%Gd NBs encountered a quite high $T_1$ shortening effect, with relaxivity being a few times greater than in commercial materials. The accessibility of water to Gd$^{3+}$ ions is the main factor in the shortening of $T_1$. It has previously been suggested that a rigid crystal lattice could greatly reduce the Gd$^{3+}$ ions’ water accessibility, resulting in a limited contribution to $T_1$ shortening. The XRD and Raman results are presented above confirmed that TiO$_2$@5%Gd NBs and TiO$_2$@10%Gd NBs are well crystallized structures and therefore have limited contribution to $T_1$ shortening; however, the TiO$_2$@15%Gd NBs here show a retained anatase structure from Raman and partly amorphous character from the broad background in XRD and TEM images, thus TiO$_2$@15%Gd NBs seem to be around the optimum composition for delivering the best MRI response as well as PL intensity.

Data in Table S1 of the Supporting Information show the same trend as $T_1$ was the shortest; $T_2$ relaxation time was found for TiO$_2$@15%Gd MBs. $T_2$ is related to the magnetic moment of the imaging contrast agents and thereby to their size. The magnetic moment of nanoparticles rapidly decreases as their sizes decrease due to the reduction in the volume magnetic anisotropy and spin disorders on the surface of the nanoparticles. In general, controlling the size of nanoparticles is critical for achieving a strong $R_2 = 1/T_2$ enhancement, where the theoretically predicted maximum of $r_2$ relaxivity can be approached by optimizing the overall size of contrast agent. The relaxivity recorded for the TiO$_2$@15%Gd NBs was surprisingly high ($r_2 = 126$ mm$^{-1}$ s$^{-1}$) compared to a commonly available contrast agent for $T_2$ shortening and could thus be promising for use as efficient MRI contrast agent. An NMRE measurement was conducted for this sample to obtain more information about its MRI function. The field dependence of the proton relaxation rate for (NMRE profile) TiO$_2$@15%Gd NBs is shown in Figure 3b. As expected, the undoped TiO$_2$ NBs show a flat NMR profile (not shown in the figure) while the 15% Gd-doped TiO$_2$ relaxivity is strongly increased and resembles a typical NMRE profile of the MRI contrast agents with highest relaxivity $r_1 = 27$ mm$^{-1}$ s$^{-1}$ at 20 MHz. It has been previously reported that densely packed nanoparticles have high magnetizations, and it is likely that the high relaxivities of TiO$_2$@15%Gd NBs also here can be attributed to the packing of the local structure, i.e., densely packed nanoparticles in cluster form as observed from Figure S1b of the Supporting Information.

### 2.3. Photocatalytic Activity of TiO$_2$@xGd NBs

To evaluate cancer cell destruction capability (based on ROS photogeneration) of synthesized structures, the photocatalytic activities of synthesized structures were quantified using a fluorescence probe method with coumarin, which is regarded as a viable indirect detection method for the presence of hydroxyl radicals. *OH is an extremely important species, being frequently assigned as the major reactant responsible for the photocatalytic oxidation of organic compounds and deactivation of microorganisms. The formation of *OH radicals on the synthesized structure surface was probed by measuring the fluorescence intensity of 7-hydroxycoumarin, produced by different synthesized structures under irradiation with UV-A, as a function of the irradiation time. Moreover, the effect of H$_2$O$_2$ on the formation of *OH radicals was investigated, and the result was presented in Figure 3b. Linear increases in the concentration of 7-hydroxycoumarin were observed as a function of the UV-A illumination time for all experiments (Figure 3a,b) where the *OH generation rate ($r$), without and with H$_2$O$_2$, was calculated from the slope of the lines (Table 1).
from the rate of •OH generation \((r)\) divided by the incident photon flux \((I_0)\), according to the following equation\(^{52,53}\)

\[
\left(\frac{r}{I_0}\right) \times 100 = \eta
\]  

(1)

The photonic efficiencies of •OH generation, without and with \(\text{H}_2\text{O}_2\), are summarized in Table 1.

The results show that in the absence of \(\text{H}_2\text{O}_2\) the photonic efficiencies of •OH generation with \(\text{TiO}_2@5\%\text{Gd NBs}\) and \(\text{TiO}_2@10\%\text{Gd NBs}\) are significantly higher than \(\text{TiO}_2\) NBs and \(\text{P}25\).\(^{53}\) Presence of \(0.1 \times 10^{-3}\ \text{m} \text{H}_2\text{O}_2\) had a contradictory effect on the formation of •OH on the different nanobeads, where the addition of \(0.1 \times 10^{-3}\ \text{m} \text{H}_2\text{O}_2\) led to a significant increase of photonic efficiencies of •OH generation with \(\text{P}25\) and pure \(\text{TiO}_2\) NBs.\(^{50}\) On the other hand, for \(\text{TiO}_2@5\%\text{Gd NBs}\) and \(\text{TiO}_2@10\%\text{Gd NBs}\), adding \(0.1 \times 10^{-3}\ \text{m} \text{H}_2\text{O}_2\) had a negative effect. In the absence as well presence of \(\text{H}_2\text{O}_2\), photonic efficiencies of •OH generation with \(\text{TiO}_2@15\%\text{Gd NBs}\) and \(\text{TiO}_2@20\%\text{Gd NBs}\) were negligible compared to other structures. From the results it is clear that low concentrations of Gd (5%–10% Gd) are beneficial for ROS generation in the photocatalytic activity of \(\text{TiO}_2\) NBs, with a maximum ROS photogeneration for 10% Gd doping, while the higher concentrations of 15% and 20% Gd lead to much lower anatase crystallinity\(^{54}\) and reduce the ROS photogeneration dramatically (Table 1 and Figure 3). The enhancement of photocatalytic activity after Gd-doping can be assigned to the higher adsorption, improved charge-transfer efficiency, and the prevention of electron–hole recombination.\(^{1}\) To further explore how the electronic changes in the Gd-doped \(\text{TiO}_2\) affect the absorption and possibly improved charge transfer and electron–hole recombination, DFT calculations were performed and analyzed for undoped and Gd-doped anatase \(\text{TiO}_2\).\(^{36,55}\)

### 2.4. DFT Calculations

Corresponding unit cells of undoped and Gd-doped \(\text{TiO}_2\) anatase are depicted in Figure 4a,d. In the case of doping, the

**Figure 4.** a) Unit cell, b) charge density distribution, c) PDOS of anatase \(\text{TiO}_2\). d) Unit cell, e) charge density distribution, f) PDOS of 12% Gd-doped anatase \(\text{TiO}_2\).
replacement of Ti with Gd within the anatase lattice is accompanied by structural changes, due to a different cation radius and charge of Gd that further affect ground-state charge density distribution and the density of states (DOS).[56] Figure 4 compares the charge density distribution within the lattice of anatase and Gd-doped anatase (Figure 4b,c), and also the corresponding calculated DOS and partial DOS (PDOS) (Figure 4e,f). By considering the atoms in the lattice as charged ions, Löwdin charge analysis can be used for estimation of the dipole moments in the lattice,[57] providing the relative magnitudes and directions of the dipoles in the doped and undoped lattices. Regarding the data presented in Figure 4, the in-plane dipole moment for the TiO\textsubscript{2} lattice was zero (due to the symmetry illustrated in Figure 4b); however, for the Gd-doped TiO\textsubscript{2} it was estimated to be 1.1 Debye (Figure 4e).

The comparison of our calculated PDOS and total DOS of anatase TiO\textsubscript{2} and Gd-doped anatase TiO\textsubscript{2} (Figure 4c,f) reveals that the Gd\textsuperscript{3+} ions introduced impurity energy levels (IELs) inside the bandgap (at the top of valence band), and that, consequently, the bandgap is slightly narrowed by Gd doping. IELs inside the bandgap of anatase TiO\textsubscript{2} consist of RE 4f states, RE 5d states, and RE 6\textsuperscript{s} states, which influence the positions, widths, and DOS of CB and VB of anatase TiO\textsubscript{2}, consistent with previous work with RE in TiO\textsubscript{2}.[55] The presence of Gd induces some structural changes in the unit cell by distorting the metal–oxygen octahedron bond lengths and angles (summarized in Table S2 of the Supporting Information for the case of 12% doping as examples). The changes in cell volume, bond length, and charge on atoms result that the center of gravity of negative electric charges deviates from the position of the Ti\textsuperscript{4+} ion in the TiO\textsubscript{2} octahedron, and its dipole moment is consequently no longer zero.[57] Charge imbalance and local permanent dipoles would facilitate more efficient charge separation upon excitation and subsequent charge transport, but it may also help OH adsorption on the surface and retard the recombination,[1] and consequently enhance the ROS photogeneration. In addition to nonzero dipole moment induced by doping (as depicted in Figure 4d by white arrows), after doping, the distribution of charge density along the covalent bond of metal–oxygen is enhanced. This is in agreement with the calculated Löwdin charge of the atoms (presented in Table S2 of the Supporting Information) and shows less ionic and more covalent nature of the bonds that can facilitate the charge transport from the bulk to the surface of the particle.[59]

2.5. Biocompatibility of TiO\textsubscript{2}@Gd NBs and Photocatalytic Treatments of Cancer Cells: In Vitro Study

The relatively low ROS photogeneration activity of the TiO\textsubscript{2}@15\%Gd and TiO\textsubscript{2}@20\%Gd NBs would make them less promising candidates for single use in PDT, but instead very promising for MRI contrast. Application of TiO\textsubscript{2}@xGd NBs in PDT with simultaneous therapeutic and imaging efficacies is desirable for the future,[54] and therefore TiO\textsubscript{2} NBs doped with high concentration were neglected, and just TiO\textsubscript{2} NBs, TiO\textsubscript{2}@5\%Gd NBs, and TiO\textsubscript{2}@10\% Gd NBs were considered for in vitro studies.

Cytotoxicity of TiO\textsubscript{2}@xGd NBs was tested by Resazurin assay and the results presented in the Figure S10 of the Supporting Information. The cytotoxicity results (Figure S10, Supporting Information) show that viability of the cell was not affected by TiO\textsubscript{2}@xGd NBs for all tested concentrations (10, 50, 75, 100, 200 μg mL\textsuperscript{−1}) and TiO\textsubscript{2}@xGd NBs fully biocompatible. There is a reverse relation between biocompatibility and size of nanostructures; smaller nanostructures with a higher surface area are more active for ROS generation, however they show more cytotoxicity. Engineered TiO\textsubscript{2}@xGd NBs avoid cytotoxicity, having a size greater than 100 nm; while, on the other hand, TiO\textsubscript{2}@xGd NBs, keeping high surface area and mesoporosity, have a high capacity for ROS photogeneration. Morphological alteration of MG-63 cells treated with different TiO\textsubscript{2}@xGd NBs was monitored with light and differential interference contrast (DIC) microscopy. Microscopy images (Figure 5b–d) proved that the morphology of MG-63 cells treated with TiO\textsubscript{2}@xGd NBs did not differ from the morphology of untreated control cells (Figure 5a), which could be explained as high biocompatibility. The most significant finding of our work is cellular internalization of TiO\textsubscript{2}@xGd NBs (Figure 5b–d), which is much more significant in the case of TiO\textsubscript{2}@10\%Gd NBs compared to the TiO\textsubscript{2}@5\%Gd NBs or undoped TiO\textsubscript{2} NBs, although all cells were treated with the same TiO\textsubscript{2}@xGd NBs concentration (50 μg mL\textsuperscript{−1}). We noticed that the majority of TiO\textsubscript{2}@xGd NBs were located around the cell nuclei (Figure 5b–d). More experiments were done to examine acid organelles after cellular treatment with TiO\textsubscript{2}@xGd NBs. Cells treated with 50 μg mL\textsuperscript{−1} of TiO\textsubscript{2}@xGd NBs and incubated for 24 h had enlarged acid organelles and compared to untreated control cells (Figure 5e–g). We speculate that enlarged acid organelles are filled with NBs, indicating that MG-63 human cancer cells endocytose NBs.[60–62] The flat spread appearance of the cells gives room for cellular inclusions only around the nucleus in a dome-shaped central part of the cell. TEM analysis was performed to confirm the internalization of NBs. Figure S11 of the Supporting Information shows a perinuclear region with TiO\textsubscript{2}@10\%Gd NBs inclusions.

Since MG-63 human cancer cells endocytose TiO\textsubscript{2}@xGd NBs, they could concentrate TiO\textsubscript{2}@xGd NBs and this can significantly improve specificity for imaging and damage cancerous cells, together with low systemic toxicity.[63] MG-63 cells incubated with TiO\textsubscript{2}@xGd NBs were irradiated with an LED lamp for a different period (3, 4, 5 min) to specific photocatalytic ROS generation inside of MG-63 cells. Upon irradiation, the excited TiO\textsubscript{2}@xGd NBs transfer energy to the surrounding O\textsubscript{2} and H\textsubscript{2}O to generate ROS, which can be exploited to destroy cancer cells.[5] The produced ROS exhibits an extremely short lifespan and severely limited diffusion distance, so the damage of ROS to biomolecules
is strongly restricted to the immediate vicinity of ROS photogeneration.\cite{11} Mitochondria are the primary source of cellular ROS generation (approximately up to 90%), and mitochondrial dysfunctions are closely correlated with the disruption in the balance of mitochondrial ROS. Also, mitochondria are decisive regulators of the intrinsic pathway of apoptosis, which is regarded as the major mode of cell death in cancer therapy.\cite{64,65} Resazurin assay is an extremely sensitive, simple, and nontoxic procedure to evaluate mitochondrial function.\cite{66} After photocatalytic treatment, the controlled manipulation of mitochondrial activity was further estimated with resazurin assay.

Resazurin assay result after photocatalytic treatment showed that survival rate of MG-63 cancer cells depends on irradiation time, and for irradiation longer than 4 min cell population in a control group suffers from UV-A irradiation (Figure 6). However, after 3 min irradiation, the cell viability in the control group was more than 90%, suggesting 3 min UV-A irradiation possessed good biocompatibility. For certain irradiation times, cells pretreated with TiO$_2$@xGd NBs were more vulnerable to UV-A irradiation; this means TiO$_2$@xGd NBs deliver their photocatalytic activity and ROS photogeneration potential for cancer cells destruction. After 3 min of UV-A irradiation, TiO$_2$@10%Gd NBs showed enhanced photocatalytic activity compared to undoped TiO$_2$ NBs and TiO$_2$@5%Gd NBs for cancer cells destruction, in good agreement with our other experiments and theoretical calculation.

3. Conclusion

The current study presents the synthesis, characterization, and performance of novel biocompatible and multifunctional Gd-doped TiO$_2$ in the sub-micrometer range, intended with a potential for cancer cells tracking and killing. Our results showed that the ROS photogeneration capacity of the TiO$_2$ NBs doped with a low concentration of Gd (5% Gd and 10% Gd) was increased compared to TiO$_2$ NBs and P25. ROS photogeneration capacity of those TiO$_2$ NBs doped with high concentration of Gd (15% and 20% Gd) significantly decreased in comparison with undoped TiO$_2$ NBs and P25, while instead providing better OI and MRI contrast effect, especially for TiO$_2$@15%Gd NBs. According to our result, we suggested TiO$_2$@10%Gd NBs as a promising candidate with high ROS photogeneration capacity and increased OI and MRI effect. Ti shortening effect of TiO$_2$@10%Gd NBs was moderate ($r_1 = 4.7$ mm$^{-1}$ s$^{-1}$); however, $T_2$ shortening effect of this sample was high ($r_2 = 80$ mm$^{-1}$ s$^{-1}$), where $r_2$ relaxation of TiO$_2$@10%Gd NBs was even a few times more than clinically available contrast agent.\cite{67} However, if target is only the imaging capabilities, the TiO$_2$@15%Gd NBs showed the largest PL intensity, as well as strong relaxation rate $1/T_2$, where $r_2$ was $126$ mm$^{-1}$ s$^{-1}$.

In vitro cytotoxicity of TiO$_2$@xGd NBs tested by measuring mitochondrial activity associated with viability assay and the results confirmed that TiO$_2$@xGd NBs are fully biocompatible for all tested concentration. Regarding ROS photogeneration capacity of TiO$_2$@xGd NBs, in agreement with
results obtained with our other experiments and theoretical calculation, TiO$_2$@10\%Gd NBs showed highest photocatalytic activity already after 3 min of irradiation with UV-A.

To the end, since TiO$_2$@xGd NBs produce ROS only when they are photoactivated, they form a fully biocompatible system for MRI and up to 3 min of irradiation in combined PDT treatment and OI–MRI, and would form a promising platform for simultaneous cancer cell imaging and treatment by PDT.

Figure 6. a) Cell viability of MG-63 cells after 1 h exposure to TiO$_2$@xGd NBs followed by UV-A radiation and 24 h postincubation, tested by resazurin assay. Results are presented as the mean (+SD) percentage of untreated, nonradiated control in the experiment performed twice in at least five replica wells. b–e) Asterisks in the lower graphs denote the significant differences between samples (*p < 0.05; **p < 0.01; ***p < 0.001; Student’s t-test). Cell viability between nonradiated samples (0 min) treated with TiO$_2$ (+ Gd) NBs did not significantly differ in comparison to untreated control.
