(Received 3 August 2001; In final form 10 January 2002)

The mathematical models and the corresponding computer program for determination of the hip joint contact force, the contact stress distribution, and the size of the weight bearing area from a standard anteroposterior radiograph are described. The described method can be applied in clinical practice to predict an optimal stress distribution after different operative interventions in the hip joint and to analyze the short and long term outcome of the treatment of various pathological conditions in the hip. A group of dysplastic hips and a group of normal hips were examined, with respect to the peak contact stress normalized by the body weight, and with respect to the functional angle of the weight bearing area. It is shown that both these parameters can be used in the assessment of hip dysplasia.

Keywords: Hip joint; Computer simulation; Contact stress distribution; Radiograph

INTRODUCTION

The hip joint is a multiaxial spheroidal joint where the articulating bone surfaces are covered with articular cartilage. A synovial membrane underlying the interior of the joint capsule secretes lubricant called synovial fluid [1]. Due to synovial fluid, the tangential stress in the hip joint articular surface is negligible compared to the normal stress [2]. In the following, the term hip joint contact stress is used for the normal stress in the hip joint articular surface.

It was indicated that an excessive hip joint contact stress is an important factor accelerating degenerative processes in the hip joint [3–5]. Also, it was found that the peak stress in the hip joint is higher in women than in men [6]. As women have a higher incidence of arthrosis, these results favor the hypothesis that elevated stress in the hip joint (due to characteristic femoral and pelvic shape) can be one of the reasons for greater incidence of arthrosis in the female population [7].

In this work, we present a computer method for estimation of peak contact stress and of the size of the weight bearing area in human hip joint in one-legged stance body position by using a standard anteroposterior roentgenograph. The contact stress distribution in the hip joint is determined in two steps. First, the hip joint resultant force \mathbf{R} is determined by solving the equilibrium

equations for forces and torques in the one-legged stance where the individual variations in the femoral and pelvic geometry are determined from standard anteroposterior roentgenographs. Second, the magnitude and direction of \mathbf{R} are used as the input data into the model for determination of stress distribution. For that, centre-edge angle (ϑ_{CE}) and the radius of the femoral head (r) should also be known. Two specific examples of application of the described computer program for determination of the contact stress distribution and the size of the weight bearing area in the human hip joint are presented: the peak contact stress in different pelvic shapes is calculated and the average peak contact stress and the average weight bearing area are estimated for the group of normal hips and for the group of dysplastic [8] hips.

DETERMINATION OF THE HIP JOINT RESULTANT FORCE FROM THE STANDARD ANTEROPOSTERIOR RADIOGRAPHS IN ONE-LEGGED STANCE

Equations of Static Equilibrium of the Body in the One-legged Stance

The origin of the Cartesian coordinate system is chosen in the femoral head center of the loaded leg so that the x and z

FIGURE 1 The characteristic forces, moment arms and geometrical parameters of the described model of the hip in one-legged stance body position.

axes lie in the frontal plane while y axis points in the posterior direction (Fig. 1). Due to simplicity, the body is divided into two segments. The first segment is the loaded leg and the second segment is the rest of the body. In the one-legged stance (Fig. 1), the second segment bears the partial body weight ($W_B - W_L$), where W_B is the body

TABLE I The relative cross-sectional areas of the model muscles

Muscle	i	Group	A_i
Gluteus medius-anterior	1	α	0.266
Gluteus minimus-anterior	2	α	0.113
Tensor fasciae latae	3	α	0.120
Rectus femoris	4	α	0.400
Gluteus medius-middle	5	β	0.266
Gluteus minimus-middle	6	β	0.113
Gluteus medius-posterior	7	γ	0.266
Gluteus minimus-posterior	8	γ	0.133
Piriformis	9	γ	0.100

weight and W_L the weight of the loaded leg. The force and moment equilibrium equations for the second segment can be written in the form [9]:

$$\sum_i \mathbf{F}_i - \mathbf{R} + (W_B - W_L) = 0, \quad (1)$$

$$\sum_i (\mathbf{r}_i \times \mathbf{F}_i) + \mathbf{a} \times (W_B - W_L) = 0, \quad (2)$$

where $\mathbf{a} = (0, 0, a)$ is the moment arm of the force ($W_B - W_L$), \mathbf{r}_i is the radius vector of the i -th muscle force (\mathbf{F}_i) application point drawn from the origin of the coordinate system to the muscle origin point on the pelvis. The model includes nine effective muscles, which are classified in three groups according to their positions: anterior (α), middle (β) and posterior (γ) (Table I). Each muscle is considered to act along straight line connecting the point of attachment on the pelvis (determined by the radius vector \mathbf{r}_i) and the point of attachment on the femur (determined by the radius vector \mathbf{r}'_i). The rotation of the pelvis in the frontal plane around y -axis is described by the angle φ while the rotation of the femur around y -axis in the frontal plane is described by the angle ϑ (Fig. 1). For $\vartheta = 0$ and $\varphi = 0$, the reference three-dimensional coordinates of the radius vectors $\mathbf{r}_i = (x_i, y_i, z_i)$ and $\mathbf{r}'_i = (x'_i, y'_i, z'_i)$ are taken from Dostal and Andrews [10]. In general, the angles ϑ and φ are not zero (Fig. 1), therefore, the reference coordinates of the muscle attachment should be corrected using the corresponding rotation matrixes. In this work, we take $\varphi = 0$ and $\vartheta = \arcsin(b/x_0)$ where $x_0 = 42.3$ cm [10] is the length of the femur and b is the z -coordinate of the moment arm of the force W_L (Fig. 1).

The force of each individual muscle included in the model is written as [9]:

$$\mathbf{F}_i = \sigma_i A_i \mathbf{e}_i, \quad (3)$$

where A_i is the relative cross-sectional area of the i -th muscle (Table I) determined from the data of Johnston *et al.* [11], σ_i is the average tension in the i -th muscle and $\mathbf{e}_i = (e_{ix}, e_{iy}, e_{iz})$ is the unit vector in the direction of the force of the i -th muscle ($i = 1, 2, \dots, 9$):

$$\mathbf{e}_i = \frac{\mathbf{r}'_i - \mathbf{r}_i}{|\mathbf{r}'_i - \mathbf{r}_i|}. \quad (4)$$

TABLE II The predicted values of the average muscle tensions (σ_i) and the magnitude of the hip joint resultant force (R) determined by the optimization method (second column) and by the reduction method (third column) and for $\ell = 16.9$ cm and $W_B = 800$ N.

Muscle (i)	Optimization σ_i (N/cm ²)	Reduction σ_i (N/cm ²)
1	111.9	36.2
2	39.8	36.2
3	34.5	36.2
4	48.1	36.1
5	102.7	191.0
6	37.6	191.0
7	78.4	14.6
8	28.9	14.6
9	15.0	14.6
R/W_B	2.370	2.383

The magnitude of the moment arm of the force ($W_B - W_L$) is determined from the y -component of the moment equilibrium equations for the first and the second body segment:

$$-W_B c + W_L b - M_Y = 0, \quad (5)$$

$$(W_B - W_L)a + M_Y = 0, \quad (6)$$

where a is z -coordinate of the moment arm $\mathbf{a} = (0, 0, a)$, c is z -coordinate of the moment arm of the ground reaction force $-\mathbf{W}_B$ (Fig. 1) and M_Y is z -component of intersegmental moment $\mathbf{M} = \sum_i (\mathbf{r}_i \times \mathbf{F}_i)$. It follows from Eqs. (5) and (6) [12]:

$$a = \frac{W_B c - W_L b}{W_B - W_L}. \quad (7)$$

The moment arms b and c are expressed by the interhip distance ℓ : $b = 0.24\ell$, $c = 0.5\ell$ [12]. The weight of the leg is approximated by the equation $W_L = 0.16 W_B$ [13].

The described mathematical model for the body in the one-legged stance static position has six scalar equations given by three components of the vector equilibrium equations (Eqs. (1) and (2)), and 12 unknowns (three components of the force $\mathbf{R} = (R_X, R_Y, R_Z)$ and nine unknown muscle tensions σ_i). The number of unknowns of the model thus exceeds the number of model equations, therefore the problem is indeterminate and in general an infinite number of solutions satisfy the system of Eqs. (1) and (2). The problem can be solved either by reducing the number of the model unknowns (reduction method) or by taking into account additional optimization criteria for the muscles' actions (optimization method).

Reduction Method

The aim of the reduction method [9] is to modify an initially indeterminate problem to a determinate one by reducing the number of unknowns. For this purpose, the average tensions (σ_i) in the particular muscle group are assumed to be equal: $\sigma_1 = \sigma_2 = \sigma_3 = \sigma_4 = \sigma_\alpha$, $\sigma_5 = \sigma_6 = \sigma_\beta$, $\sigma_7 = \sigma_8 = \sigma_9 = \sigma_\gamma$. The equilibrium equations (Eqs. (1) and (2)) can be then solved and the unknown quantities R_X , R_Y , R_Z , σ_α , σ_β and σ_γ are obtained (Table

II). The calculated \mathbf{R} turned out to be lying nearly in the frontal plane of the body and its sagittal component did not exceed 1% of the frontal component in one-legged stance [9].

Optimization Method

Another procedure used to solve an initially indeterminate problem (Eqs. (1) and (2)) is the optimization method [11, 14]. In this study, we select the nonlinear optimization criteria of minimal possible magnitude of the hip joint contact force [15], i.e. the criteria of the minimal possible bone loading. Due to simplicity, we are searching for the minimum of the square of magnitude of the hip joint reaction force:

$$F = \left(\sum_{i=1}^9 \sigma_i A_i e_{ix} + (W_B - W_L) \right)^2 + \left(\sum_{i=1}^9 \sigma_i A_i e_{iy} \right)^2 + \left(\sum_{i=1}^9 \sigma_i A_i e_{iz} \right)^2, \quad (8)$$

subject to three constraints (Eq. (2)):

$$G_1 = \sum_{i=1}^9 (Y_i \sigma_i A_i e_{iz} - z_i \sigma_i A_i e_{iy}) = 0 \quad (9)$$

$$G_2 = \sum_{i=1}^9 (z_i \sigma_i A_i e_{ix} - x_i \sigma_i A_i e_{iz}) + a(W_B - W_L) = 0 \quad (10)$$

$$G_3 = \sum_{i=1}^9 (x_i \sigma_i A_i e_{iy} - y_i \sigma_i A_i e_{ix}) = 0 \quad (11)$$

In order to solve the described optimization problem, we used the constrained Fletcher–Powell algorithm [16] where a modified objective function is defined as:

$$\Phi = F - \sum_{k=1}^3 \lambda_k G_k + B \sum_{k=1}^3 G_k^2, \quad (12)$$

where λ_k and B are parameters. When the convergence is achieved $G_k = 0$ and $F = \Phi$. The values of σ_i and R determined by this optimization technique are given in Table II. It can be seen in Table II that the calculated values of σ_i by using the reduction method and by using the optimization technique are considerably different. However, the predicted values of R/W_B do not differ that much. Since in this work, we are interested only in the hip joint resultant force, in the following \mathbf{R} is calculated using the simple reduction method.

Determination of the Hip Joint Resultant Force for an Individual Patient Using the Standard Anteroposterior Radiograph

The calculated hip joint resultant force \mathbf{R} should be scaled by the individual variations in femoral and pelvic

geometry [6,17,18]. For this reason, the reference values of the model muscle attachment points [10] and the interhip distance ℓ are rescaled in order to adjust the configuration of the hip and pelvis for the individual person. Thereby, the following values of the hip and pelvic geometrical parameters from the standard anteroposterior roentgenograph of a given patient are measured (Fig. 2): the interhip distance (ℓ), the pelvic height (H), the pelvic width (C), the vertical and the horizontal distance from the center of the femoral head to the effective muscle attachment point (T) on the greater trochanter (z and x , respectively). The point T is determined by the intersection of the contour of the greater trochanter and the normal through the midpoint of the straight line connecting the most lateral point (point 1) and the highest point (point 2) on the greater trochanter [17,18]. The above-described geometrical parameters are used to scale the respective reference values of the attachment points of the muscles included in the model (Table I) and the interhip distance for an individual person. The reference values of H , C , ℓ , z and x are adopted from Dostal and Andrews [10] and Kersnič *et al.* [7]. While taking the roentgenograph, both femurs should be in the zero joint configuration where the straight line connecting the femoral head center and the midpoint between the lateral and medial epicondyle is perpendicular to the straight line through both femoral head centers [10]. The abduction or adduction of the legs from this reference configuration would affect the accuracy of the correct values of the coordinates of the point T , i.e. z and x .

DETERMINATION OF THE CONTACT STRESS DISTRIBUTION AND THE FUNCTIONAL ANGLE OF THE WEIGHT BEARING AREA OF THE HIP JOINT

As it is mentioned above, the input parameters of the mathematical model for calculation of the hip stress distribution and for calculation of the size of the weight bearing area in the hip joint are the magnitude of the resultant hip force \mathbf{R} , the direction of \mathbf{R} represented by its inclination with respect to the sagittal plane (ϑ_R), the center edge angle ϑ_{CE} and the radius of the femoral head r (Fig. 2). The hip joint resultant force \mathbf{R} is considered to be lying in the frontal plane.

Within the model of stress distribution used in this work [19], it is assumed that when unloaded, the acetabular shell and the femoral head have spherical shape with coincident centers. Upon loading, the intermittent cartilage layer is squeezed. The contact hip stress at any point of the weight-bearing area (p) is proposed to be proportional to strain in the cartilage layer. The point of closest approach of the spherical surfaces of the acetabulum and the femoral head is called the stress pole with the spherical coordinates Θ and Φ [19]. The polar angle Θ determines the angular displacement of the pole from the vertical axis, while the azimuthal angle Φ

FIGURE 2 The geometrical parameters of the hip and pelvis needed for determination of the hip joint resultant force and contact stress distribution in the hip joint. The stress distribution and the resultant hip joint force \mathbf{R} are also shown schematically. Symbol ϑ_R denotes the inclination of \mathbf{R} with respect to the vertical.

describes the angular displacement of the pole in the horizontal plane from the frontal plane in the counter-clockwise direction. The above assumptions lead to the cosine dependency of the contact stress distribution in the hip joint [19,20]:

$$p = p_o \cos \gamma, \quad (13)$$

where p_o is the value of stress in the pole and γ is the angle between a given point and the stress pole. The lateral border of the weight-bearing area is determined by the acetabular geometry, while the medial border is defined as the curve where stress vanishes, i.e. where $\cos \gamma = 0$. With known magnitude and direction of \mathbf{R} , the distribution of the contact stress in the hip joint can be computed from the equation

$$\int_S p dS = \mathbf{R}, \quad (14)$$

where we integrate over the weight-bearing area. The solution of the system of Eqs. (13) and (14) [19] yields (for the case when \mathbf{R} lies in the frontal plane and when pole lies on the lateral side of the acetabular contact hemisphere or outside the acetabular contact hemisphere in the lateral direction) the spherical coordinate of the stress pole (Θ) and the value of stress at the pole (p_o):

$$\tan(\vartheta_R + \Theta) = \frac{\cos^2(\vartheta_{CE} - \Theta)}{\frac{\pi}{2} + \vartheta_{CE} - \Theta + \sin(\vartheta_{CE} - \Theta)\cos(\vartheta_{CE} - \Theta)} \quad (15)$$

$$p_o = \frac{3 R \cos(\vartheta_{CE} + \Theta)}{2r^2 \left(\frac{\pi}{2} + \vartheta_{CE} - \Theta + \sin(\vartheta_{CE} - \Theta)\cos(\vartheta_{CE} - \Theta) \right)}. \quad (16)$$

FIGURE 3 Schematic representation of the functional angle of the weight bearing area ϑ_F and the spherical coordinate of the pole Θ .

Since \mathbf{R} is limited to the frontal plane, the pole of stress distribution also lies in the frontal plane and is therefore determined only by one spherical coordinate, i.e. by the angle Θ (Fig. 3). The value of Θ (Fig. 3) is determined numerically from Eq. (15) using the Newton iteration method. If the pole of stress distribution is located within the weight bearing area, the location of the peak contact stress (p_{\max}) coincides with the location of the pole ($p_{\max} = p_o$). When the stress pole lies outside the weight bearing area, the peak contact stress is located at the point on the weight bearing surface, which is closest to the pole [19].

In the following, we introduce also the functional angle of the weight bearing area ϑ_F :

$$\vartheta_F = \pi/2 + \vartheta_{CE} - \Theta, \quad (17)$$

which is equal to the size of the weight bearing area divided by $2r^2$ (Fig. 3).

RESULTS AND CONCLUSIONS

In order to illustrate the ability of the presented mathematical models and the corresponding computer program HIPSTRESS (written in TURBO PASCAL and in VISUAL BASIC), to simulate the effect of the femoral and pelvic shape on the contact stress distribution in the hip joint, Fig. 4 shows the dependence of the magnitude (R) and the direction (ϑ_R) of the hip joint contact force and of the peak stress in the hip joint (p_{\max}) on the variation of the interhip distance ($\delta\ell$). It can be seen in Fig. 4 that the peak stress in the human hip joint articular surface p_{\max} has a minimal value for the pelvis with a small interhip distance and a maximal value for the pelvis with a large interhip distance. It can be also seen in Fig. 4 that the change of the interhip distance ($\delta\ell$) considerably influences the magnitude of the resultant hip joint force (R), however, it has nearly no effect on the angle of the inclination of this force with respect to the sagittal plane of

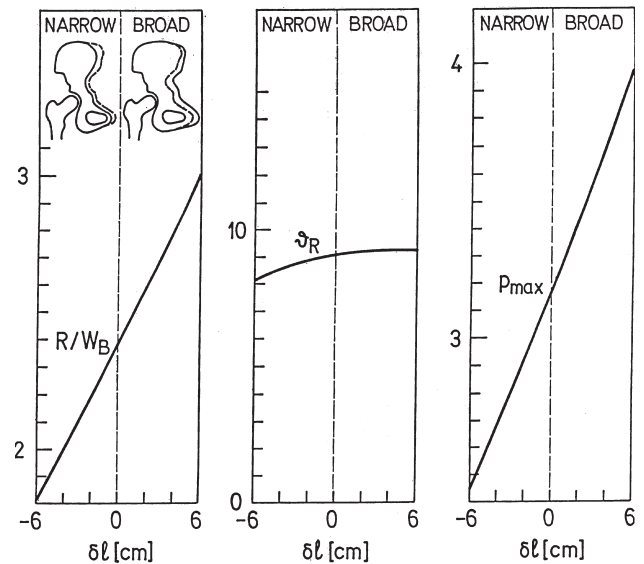

FIGURE 4 The magnitude of the resultant hip joint force (R), the angle of the inclination of the hip joint resultant force with respect to the sagittal plane of the body (ϑ_R) and the peak stress in the articular surface of the human hip joint (p_{\max}) as functions of the change of the reference interhip distance ($\delta\ell$). Parameters used in calculations are: $r = 2.5$ cm, $\vartheta_{CE} = 29^\circ$ and body weight $W_B = 800$ N.

the body (ϑ_R). This is reflected also in the peak stress in the articular surface of the hip joint (p_{\max}) which increases proportionally to R . Namely, p_{\max} is for constant ϑ_R directly proportional to R (see Eqs. (13) and (16)). The reason that ϑ_R remains nearly constant upon the change of the interhip distance ℓ is that the relative position of the hip abductor muscle origin and the insertions points remain unchanged upon the variation of the interhip distance ℓ , as they are located on the lateral side of the pelvis and on the femur. On the basis of the results presented in Fig. 4, we would like to emphasize that the pelvic shape with a large interhip distance is most probably unfavorable regarding the degenerative changes in the hip joint because of the increased stress in the articular surface of the joint.

In the following, the peak stress in the hip joint (p_{\max}) is estimated from the standard anteroposterior roentgenographs for a group of normal hips and for a group of dysplastic hips. Dysplasia of the hip refers to mechanical deformations and deviations in the size and shape or mutual proportions between the upper part of the femur and the acetabulum [8]. The dysplastic hip can be diagnosed according to anatomical changes in the hip that are visible in the radiograph, as for example the presence of osteophytes or according to the shape and density of the trabecular net in the femur [8,21,22]. The main radiographic parameter that is used for assessment of the hip dysplasia is the centre-edge angle ϑ_{CE} [21,22]. The size of ϑ_{CE} gives the numerical value of the lateral coverage of the femoral head (Fig. 2). The range from 20 to 25° is considered to be a lower limit for normal hips, while a value below 20° is pathognomonic for hip dysplasia [22]. However, it was suggested that beside ϑ_{CE} , the radius of

FIGURE 5 The correlation between the normalized peak contact stress p_{\max}/W_B and the centre-edge angle ϑ_{CE} . The values for the normal hips are denoted by the symbol \diamond and the values for the dysplastic hips are denoted by the symbol \triangle .

the femoral head should also be taken into account in assessment of hip dysplasia [22]. It was shown that in the normal hips ϑ_{CE} correlates with the femoral head radius. Hips with large heads were found to have smaller ϑ_{CE} [22]. The radiographic parameters used in assessment of hip dysplasia were actually introduced to estimate the physical quantities such as hip joint contact stress distribution and size of the weight bearing area [21]. The direct estimation of physical quantities such as the peak contact stress in the hip joint p_{\max} and the functional angle ϑ_F , could be important in assessment of hip dysplasia.

In this work, a group of dysplastic hips and a group of normal hips were examined with respect to the normalized peak contact stress p_{\max}/W_B and with respect to the functional angle of the weight bearing area ϑ_F . The correlation between the parameters p_{\max}/W_B (and ϑ_F) and the centre-edge angle ϑ_{CE} was studied. The standard anteroposterior radiographs of dysplastic and normal hips were taken from the medical records of the Department of Orthopaedic Surgery and Department of Traumatology, University Medical Centre, Ljubljana. The group of dysplastic hips consists of 20 subjects with unilateral dysplasia and 18 subjects with bilateral dysplasia. In total, we have 56 dysplastic hips. In this group, 9 hips belong to males and 47 belong to females, 32 hips are right and 24 are left. The normal hips belong to 146 persons who were subject to the X-ray examination of the pelvic region for reasons other than degenerative diseases of the hip joint. The radiographs showed no signs of the hip pathology. The contours of the bony structures in each anteroposterior radiograph were put into digital form and then measurements of the geometrical parameters (Fig. 2) were performed. The geometrical parameters needed for determination of the resultant hip force (Fig. 2) are the

interhip distance (ℓ), the pelvic height (H), the pelvic width (C) and the coordinates of the effective muscle attachment point on the greater trochanter (T). Digitization of the contours from the radiographs and determination of the geometrical parameters were performed by using a computer program HIJOMO as described in detail elsewhere [6,18]. The same program HIJOMO was also used to determine the centre-edge angle ϑ_{CE} and the femoral head radius r needed for calculation of the parameter p_{\max}/W_B and the functional angle ϑ_F .

The correlation between the centre-edge angle ϑ_{CE} and the normalized peak contact stress p_{\max}/W_B is shown in Fig. 5. The shape of the numerically obtained fitting curve is consistent with the above-described mathematical model of the contact stress distribution in the hip joint. Low ϑ_{CE} correlates with high p_{\max}/W_B and vice versa. Scattering of the data in Fig. 5 shows that in determining the peak contact stress, the geometrical parameters other than ϑ_{CE} angle are also important. For example, in two hips with approximately the same ϑ_{CE} (6°) the normalized peak stress was shown to differ by about 4000 m^{-2} . The influence of the geometrical parameters other than ϑ_{CE} on the value of p_{\max}/W_B is larger for smaller ϑ_{CE} angles.

Figure 6 shows the correlation between the centre-edge angle ϑ_{CE} and the functional angle of the weight bearing ϑ_F . In Fig. 6, we can see a positive correlation between ϑ_F and ϑ_{CE} ; high values of ϑ_{CE} correlate with high values of ϑ_F . The influence of the geometrical parameters other than ϑ_{CE} on the functional angle ϑ_F (reflected in the scattering) is low.

To characterize the role of the parameters p_{\max}/W_B and ϑ_F in the assessment of hip dysplasia, statistical significance of the differences in the parameters p_{\max}/W_B and ϑ_F between the normal and dysplastic hips

FIGURE 6 The correlation between the functional angle of the weight bearing ϑ_F and the centre-edge angle ϑ_{CE} . The values for the normal hips are denoted by the symbol \diamond and the values for the dysplastic hips are denoted by the symbol Δ .

was calculated by the two-tailed pooled t -test [23]. The average values of the sets of the data of the particular biomechanical parameter and the results of the t -test are given in Table III. The null hypothesis [8] assuming equal average values of p_{\max}/W_B and ϑ_F in normal and dysplastic hips is rejected at the level lower than 0.001. It can be therefore concluded that parameters p_{\max}/W_B and ϑ_F are appropriate biomechanical parameters for the assessment of hip dysplasia.

The normalized peak contact stress p_{\max}/W_B and the size of the weight bearing area (which is proportional to ϑ_F) have been estimated from the anteroposterior radiographs already before [20,22]. However, in these studies the hip joint contact force was determined by using the simple mathematical models, which consider only a single effective muscle group (the hip abductors) and very few direct musculoskeletal anatomical data. Consequently, the variation of the model parameters by means of the variation of the geometrical parameters of the femoral and pelvic shape is strongly limited [24]. More accurate estimation of the hip joint contact force requires three-dimensional muscle model [11,24]. In this work, the hip joint contact force is calculated by using a three-dimensional mathematical model that includes nine effective muscles (Table I). The coordinates of the muscle pelvic and femoral attachment points are taken from Dostal and Andrews [10].

TABLE III The average values of p_{\max}/W_B and ϑ_F in the normal and dysplastic hips

Parameter	Normal	Dysplastic	Difference (P)
p_{\max}/W_B (m^{-2})	2692	5274	<0.001
ϑ_F (degree)	117	66.8	<0.001

In conclusion, we describe a method for determination of the hip joint contact force, the peak contact stress and the functional angle of the weight bearing area from the standard anteroposterior radiographs by using the mathematical model. A population study indicated that by applying the described method the average value of the normalized peak contact stress p_{\max}/W_B and the average value of the functional angle of the weight bearing ϑ_F are in dysplastic hips twice as large as the respective quantities in normal hips. It was also indicated that the pelvic shape with a large interhip distance is most probably unfavorable regarding the degenerative changes in the hip joint because of the increased stress in the articular surface of the joint.
